COMP 110

More Practice with Recursive Functions

Reminders:

- Tutoring @5-7PM today and tomorrow
- Virtual review session tomorrow (11/21) at 7pm
 - Link on the site's agenda!

Welcome to Dog110!

The COMP110 dogs went to daycare and each dog's behavior was scored on a scale of 1-10. If all 3 dogs scored at least an 8, we'll pet them 110 times. Let's write a recursive function to see if all dogs in the list were good today!

Nelli Ada

Pip

Welcome to Dog110!

The COMP110 dogs went to daycare and each dog's behavior was scored on a scale of 1-10. If all 3 dogs scored at least an 8, we'll pet them 110 times. Let's write a recursive function to see if all dogs in the list were good today!

3 parameters:

- scores: list[dict[str, str]]
 - list of dictionaries of dogs' names and scores;
- thresh: int
 - Threshold we're using to determine if a dog was good
- idx: int
 - Index of dog of interest for the function call

Example usage:

```
print(all_good(scores=pack, thresh=8, idx=0)) would return False
print(all_good(scores=pack, thresh=7, idx=0)) would return True
```

all good Algorithm

Let's write a recursive function to see if all dogs in the list were good today!

Example usage:

```
print(all_good(scores=pack, thresh=8, idx=0)) would return False
print(all_good(scores=pack, thresh=7, idx=0)) would return True
```

Conceptually, what will our base case be?

What will our **recursive case** be?

What is an edge case for this function? How could we account for it?

Visualizing recursive calls to all good

Values

idx = 2

```
all good(scores=pack, thresh=8, idx=0) returns False
                 scores[0]["score"] >= thresh. Good dog, Nelli!
                     Now, let's check the next dict in the list...
                    return all good(scores, thresh, idx + 1)
                    return all good(scores, thresh, 1)
                    return False
                                          scores[1]["score"] >= thresh. Good dog, Ada!
                                              Now, let's check the next dict in the list...
                                      return all good(scores, thresh, idx + 1)
                                      return all good(scores, thresh, 2)
thresh = 8
                                      return False
                                                           scores[2]["score"] < thresh...</pre>
                                                           not all dogs were good!
pack: list[dict[str, str]] = [
   {"name": "Nelli", "score": "10"},
                                                        return False
   {"name": "Ada", "score": "9"},
   {"name": "Pip", "score": "7"},
```

Let's write the all_good function together!

Memory diagram

```
def all_good(scores: list[dict[str, str]], thresh: int, idx: int) -> bool:
    num_dogs: int = len(scores)
    if num_dogs <= idx:</pre>
        raise IndexError("idx too high!")
    elif int(scores[idx]["score"]) < thresh:</pre>
        return False
        if num_dogs == idx + 1:
            return True
            print(f"Good dog, {scores[idx]["name"]}!")
            return all_good(scores, thresh, idx + 1)
pack: list[dict[str, str]] = [
    {"name": "Nelli", "score": "10"},
    {"name": "Ada", "score": "9"},
    {"name": "Pip", "score": "7"},
print(all_good(scores=pack, thresh=8, idx=0))
```

Visualizing recursive calls to all_good

When developing a recursive function:

Base case:

- Does the function have a clear base case?
 - ☐ Ensure the base case returns a result directly (without calling the function again).
- Will the base case always be reached?

Recursive case:

- Ensure the function moves closer to the base case with each recursive call.
- Combine returned results from recursive calls where necessary.
- ☐ Test the function with edge cases (e.g., empty inputs, smallest and largest valid inputs, etc.). Does the function account for these cases?
